Abstract. This paper presents an overview of the radiative transfer problem of calculating the spectral line intensity and polarization that emerges from a (generally magnetized) astrophysical plasma composed of atoms and molecules whose excitation state is significantly influenced by radiative transitions produced by an anisotropic radiation field. The numerical solution of this non-LTE problem of the 2nd kind is facilitating the physical understanding of the second solar spectrum and the exploration of the complex magnetism of the extended solar atmosphere, but much more could be learned if high-sensitivity polarimeters were developed also for the present generation of night-time telescopes. Interestingly, I find that the population ratio between the levels of some resonance line transitions can be efficiently modulated by the inclination of a weak magnetic field when the anisotropy of the incident radiation is significant, something that could provide a new diagnostic tool in astrophysics.

1. INTRODUCTION

The non-LTE problem of the 1st kind is that described in Mihalas's (1978) book [1]: it consists in calculating, at each spatial point of the astrophysical plasma model under consideration, the values of the atomic level populations that are consistent with the intensity of the radiation field generated within the medium. This requires solving jointly the radiative transfer (RT) equations for the specific intensities and the statistical equilibrium equations for the level populations. Nowadays, this non-local and non-linear problem is routinely solved via the application of "clever" iterative schemes, where everything goes as simply as in the Λ -iteration method, but for which the convergence rate is extremely high [e.g., the reviews by 2, 3]. The success of this international meeting to honor Prof. Dimitri Mihalas on the occasion of his 70th birthday is a clear demonstration that the numerical solution of this multilevel radiative transfer problem has enabled many important advances to be made in 20th century astrophysics, including the modeling of the Fraunhofer spectrum and the development of the field of astrophysical spectroscopy.

¹ Invited review paper published in *Recent Directions in Astrophysical Quantitative Spectroscopy and Radiation Hydrodynamics*. Proceedings of the International Conference in Honor of Dimitri Mihalas for His Lifetime Scientific Contributions on the Occasion of His 70th Birthday. Editors: I. Hubeny, J. M. Stone, K. McGregor and K. Werner. *American Institute of Physics*. AIP Conference Proceedings 1171, pp. 27 – 42, (2009).

In contrast, the non-LTE problem of the 2nd kind is still rather unfamiliar to astrophysicists. This term was introduced by Landi Degl’Innocenti [4] to refer to the formidable numerical problem that implies calculating, at each spatial point of the (generally magnetized) astrophysical plasma model under consideration, the values of the $(2J + 1)^2$ elements of the atomic density matrix corresponding to each atomic level of total angular momentum J , which quantify its overall population, the population imbalances between its magnetic sublevels, and the quantum coherences between each pair of them. The values of such density-matrix elements have to be consistent with the intensity, polarization and symmetry properties of the radiation field generated within the medium. This requires solving jointly the RT equations for the Stokes parameters and the statistical equilibrium equations for the elements of the atomic density matrix². Although much remains to be done, the numerical solution of the non-LTE problem of the 2nd kind is facilitating the physical understanding and modeling of the so-called *second solar spectrum*, as well as the development of the field of astrophysical spectropolarimetry.

As clarified below, the second solar spectrum is the observational signature of radiatively induced population imbalances and quantum coherences in the atoms and molecules of the solar atmosphere. Magnetic fields produce partial decoherence via the Hanle effect, giving rise to fascinating observable effects in the emergent spectral line polarization. Interestingly, these effects allow us to “see” magnetic fields to which the Zeeman effect is blind within the limitations of the available instrumentation [e.g., 5]. In fact, the Zeeman effect is of limited practical interest for the exploration of magnetic fields in hot (e.g., chromospheric and coronal) plasmas because the polarization that it induces in a spectral line scales with the ratio between the Zeeman splitting and the Doppler width, and this ratio turns out to be particularly small in such plasmas. Moreover, the polarization of the Zeeman effect as a diagnostic tool is blind to magnetic fields that are randomly oriented on scales too small to be resolved. We may thus define “the Sun’s hidden magnetism” as all the magnetic fields of the extended solar atmosphere that are impossible to diagnose via the consideration of the Zeeman effect alone.

2. THE SECOND STELLAR SPECTRUM

Figure 1 contrasts the Fraunhofer spectrum (i.e., the visible intensity spectrum of the Sun with its multitude of absorption lines) with the so-called second solar spectrum, which is the linearly polarized spectrum observed by Stenflo and collaborators in “quiet” regions of the solar atmosphere [see 6, 7, 8, 9]. The fractional linear polarization (Q/I) of the bottom panel shows a number of conspicuous peaks on top of an *apparently noisy* Q/I

² Note that the first Stokes parameter, I , is the specific intensity at a given wavelength, while Stokes Q represents the intensity difference between linear polarization parallel and perpendicular to a given reference direction (e.g., the direction perpendicular to the straight line joining the solar disk center with the observed point). Stokes U would be then the intensity difference between linear polarization at $+45^\circ$ and -45° with respect to the chosen reference direction, where positive angles are measured counterclockwise by an observer facing the radiation. Stokes V is the intensity difference between right-handed and left-handed circular polarization.

FIGURE 1. The visible Fraunhofer spectrum (displayed as the normalized intensity of the continuum) versus the second solar spectrum (displayed as the fractional linear polarization, Q/I). The positive direction for the Stokes Q parameter is the parallel to the observed solar limb. Extracted from [8].

background. Such Q/I peaks correspond to $\lambda 6562.8$ (H_α), $\lambda 5890$ (Na I D_2), $\lambda 5644.14$ (Ti I), $\lambda 5565.48$ (Ti I), $\lambda 5535.51$ (Ba I), $\lambda 5167.32$ (Mg I), $\lambda 4758.12$ (Ti I) and $\lambda 4742.79$ (Ti I). For example, the left panels of Fig. 2 show an enlarged portion around the wavelengths of the sodium doublet. Similarly rich Q/I spectral structure is found in many other spectral regions, especially at wavelengths smaller than $5300 \text{ \AA}$ (e.g., see the right panels of Fig. 2, which show the Q/I profiles produced by Y II , Cr I and Fe I). Clearly, the second solar spectrum has a structural richness that often exceeds that of the ordinary intensity spectrum on which most of our astrophysics is based. It is also of interest to note that the linear polarization amplitudes tend to increase towards the blue and near-UV spectral regions. For example, between $3910 \text{ \AA}$ and $4630 \text{ \AA}$ we find spectral lines with Q/I amplitudes of the order of 1%, such as $\text{Ca I } \lambda 4227$, $\text{Sr II } \lambda 4078$, $\text{Ba II } \lambda 4554$ and $\text{Sr I } \lambda 4607$ [see 9].

As is well known, the polarization of the Zeeman effect is due to the wavelength shifts between the π ($\Delta M = M_u - M_l = 0$) and $\sigma_{b,r}$ ($\Delta M = \pm 1$) transitions³. The typical observational signature of the circular polarization produced by the longitudinal Zeeman effect is an antisymmetric Stokes $V(\lambda)$ profile whose amplitude scales with the ratio, $\mathcal{R}$, between the Zeeman splitting and the Doppler broadened line width. The linear polarization amplitudes of the transverse Zeeman effect scale instead as $\mathcal{R}^2$ and its

³ Such wavelength shifts are due to the presence of a magnetic field, which causes the atomic energy levels to split into different magnetic sublevels characterized by their magnetic quantum number M .

FIGURE 2. The two left panels are enlarged portions of Fig. 1 showing the complex Q/I structure across the sodium doublet, while the two right panels focus on a very interesting spectral region showing lines of Y II, Cr I and Fe I.

typical observational signatures are symmetric Stokes $Q(\lambda)$ and $U(\lambda)$ profiles with their wing lobes of opposite sign to the line center one.

As seen in the bottom panels of Fig. 2, the linear polarization signals of the second solar spectrum have nothing to do with the transverse Zeeman effect. This can also be seen in Fig. 3, which shows a high-sensitivity spectropolarimetric observation of the solar limb atmosphere in the strongest (8542 Å) chromospheric line of the Ca II triplet. The observed Stokes V/I profiles are clearly caused by the longitudinal Zeeman effect, but the Stokes Q/I and U/I signals have Gaussian-like shapes at almost all spatial positions along the direction of the spectrograph's slit. Interestingly, while the Stokes Q/I signal changes its amplitude but remains always positive along that spatial direction, the sign of the Stokes U/I signal fluctuates.

The shapes of the Q/I profiles of the second solar spectrum are not always Gaussian-like, however. A classification of the various Q/I shapes of atomic lines has been recently proposed by [11]. Strong resonance lines tend to show a triple peak structure, as is the case with the Na I D_2 line shown in the bottom left panel of Figure 2. However, the shape of the observed Q/I and U/I profiles may also show spatial variability, as illustrated in Fig. 4 for the chromospheric K-line of Ca II. Note that in this near-UV line there is no measurable hint of the longitudinal Zeeman effect, in contrast with the case of the near-IR line of Fig. 3 whose line center Stokes Q/I and U/I signals also originate in the bulk of the solar chromosphere.

3. THE PHYSICAL ORIGIN OF THE 2ND STELLAR SPECTRUM

If the second solar spectrum is not caused by the Zeeman effect, then what could its physical origin be?

FIGURE 3. Spectropolarimetric observation of the Ca II 8542 Å line in a very quiet region close to the solar limb, obtained with the Zürich Imaging Polarimeter (ZIMPOL) at the Franco-Italian telescope THEMIS of the Observatorio del Teide (Tenerife; Spain). The reference direction for Stokes Q is the tangent to the closest limb. From [10].

3.1. Atomic level polarization and anisotropic radiation pumping

In stellar atmospheres there is another fundamental mechanism, besides the Zeeman effect, producing polarization in spectral lines. There, where the emitted radiation can escape through the stellar surface, the atoms are illuminated by an anisotropic radiation field. The ensuing radiation pumping produces population imbalances among the magnetic substates of the energy levels (that is, atomic level polarization), in such a way that the populations of substates with different values of $|M|$ are different. This is termed *atomic level alignment*. As a result, the emission process can generate linear polarization in spectral lines without the need for a magnetic field. This is known as scattering line polarization [e.g., 13, 14]. Moreover, radiation is also selectively absorbed when the lower level of the transition is polarized [15, 16, 17, 18]. Thus, the medium becomes dichroic simply because the light itself has the chance of escaping from it.

The fact that the illumination of the atoms in a stellar atmosphere is anisotropic is easy to understand if we consider the case of a plasma structure embedded in the optically thin outer layers (e.g., a solar coronal filament), because the incident radiation comes mainly from the underlying quiet photosphere and is contained within a cone of half aperture $\alpha \leq 90^\circ$, with the vertex centered on the point under consideration. The larger the height above the visible stellar “surface” the smaller α and the larger the anisotropy factor $w = \sqrt{2}J_0^2/J_0^0$, where $J_0^0 = \oint \frac{d\vec{\Omega}}{4\pi} I_{v,\vec{\Omega}}$ is the familiar mean intensity and $J_0^2 \approx \oint \frac{d\vec{\Omega}}{4\pi} \frac{1}{2\sqrt{2}} (3\mu^2 - 1) I_{v,\vec{\Omega}}$, with $\mu = \cos\theta$ being the cosine of the angle between the ray and the stellar radius vector (hereafter, the vertical direction). Neglecting the $\vec{\Omega}$ dependence of the incident intensity $I_{v,\vec{\Omega}}$, and assuming that it is unpolarized, it is easy to find that $w = [1 + \cos\alpha]\cos\alpha/2$, which shows that in this case $0 \leq w \leq 1$, with $w = 1$ for the limiting case of a unidirectional unpolarized light beam that propagates along the vertical direction.

The radiation field is also anisotropic within a stellar atmosphere itself (i.e., at heights where the overlying atmospheric plasma is not optically thin), but in this case w can be positive or negative. As shown in the right panel of Fig. 5, at such heights the radiation propagating outwards shows limb darkening (i.e., it is predominantly *vertical*) while that propagating inwards shows limb brightening (i.e., it is predominantly *horizontal*). Therefore, there is competition, because “vertical” rays (i.e., with $|\mu| > 1/\sqrt{3}$) make positive contributions to w , while “horizontal” rays (i.e., with $|\mu| < 1/\sqrt{3}$) make negative contributions to w . As seen in Fig. 4 of [19], the larger the gradient of the source function the greater the anisotropy factor of the pumping radiation field, and the larger the amount of atomic level polarization. Therefore, at a given height in the inhomogeneous solar photosphere, the anisotropy factor of the solar *continuum radiation* in the (granular) upflowing regions is significantly larger than in the (intergranular) downflowing plasma [see fig. 2 of 5].

A useful expression to estimate the amplitude of the emergent fractional linear polarization is the following generalization of the Eddington-Barbier formula, which establishes that the emergent Q/I at the line center of a sufficiently strong spectral line when observing along a line of sight specified by $\mu = \cos\theta$ is approximately given by [see 19]:

$$Q/I \approx \frac{3}{2\sqrt{2}} (1 - \mu^2) [w_{J_u J_\ell}^{(2)} \sigma_0^2(J_u) - w_{J_l J_u}^{(2)} \sigma_0^2(J_l)], \quad (1)$$

where $w_{J_u J_\ell}^{(2)}$ and $w_{J_l J_u}^{(2)}$ are numerical factors that depend on the angular momentum values (J) of the lower (l) and upper (u) levels of the line transition (e.g., $w_{10}^{(2)} = 1$, $w_{01}^{(2)} = 0$ and $w_{11}^{(2)} = -1/2$), while $\sigma_0^2 = \rho_0^2/\rho_0^0$ quantifies the *fractional atomic alignment* of the upper or lower level of the line transition under consideration⁴. Note that the σ_0^2 values in Eq.

⁴ For example, $\rho_0^0(J=1) = (N_1 + N_0 + N_{-1})/\sqrt{3}$ and $\rho_0^2(J=1) = (N_1 - 2N_0 + N_{-1})/\sqrt{6}$, where N_1 , N_0 and N_{-1} are the populations of the magnetic sublevels of a level with $J=1$.

FIGURE 5. The emergent Q/I profiles (for a line of sight with $\mu = 0.1$) of three line transitions calculated in a model atmosphere with $T = 6000$ K and $B = 0$ G. All these Q/I signals are solely due to the atomic level polarization that results from the anisotropic illumination illustrated in the right panel. Left panel: assuming that the lower level is unpolarized. Middle panel: taking into account the full impact of lower-level polarization. The reference direction for Stokes Q is the parallel to the closest stellar limb. From [16].

(1) are those corresponding to the atmospheric height where the line center optical depth is unity along the line of sight.

Consider the three line transitions of Fig. 5, and the corresponding emergent Q/I profiles obtained by solving numerically the scattering polarization problem in an unmagnetized model atmosphere assuming a two-level atomic model for each line independently. The left panel corresponds to calculations carried out assuming that the lower level is completely unpolarized, while the middle panel takes into account the full impact of lower-level polarization. Note that when the atomic polarization of the lower level is taken into account then the “null line” (i.e., the one which has unpolarized emission because it has $J_u = 0$) shows the largest Q/I amplitude. Isn’t it fascinating? I mean the fact that “zero-field” dichroism (i.e., differential absorption of polarization components in the absence of any significant Zeeman splitting) is a very efficient mechanism for producing linear polarization in the spectral lines that originate in a stellar atmosphere.

3.2. The Hanle effect

In order to understand what the Hanle effect is it is first necessary to clarify that in the general case where polarization phenomena are taken into account, the full description of an atomic system requires us to specify, for each J -level, a density matrix with $(2J + 1)^2$

elements⁵. The diagonal ones, $\rho_J(M, M)$, quantify the populations of the individual sublevels and the non-diagonal ones, $\rho_J(M, M')$, the quantum coherences between each pair of them. We say that the quantum coherence $\rho_J(M, M')$ is non-zero when the atomic wave function presents a well defined phase relationship between the pure quantum states $|JM\rangle$ and $|JM'\rangle$. The law of transformation of the density-matrix under a rotation of the reference system chosen for the specification of its elements indicates that it is actually very common to find non-zero coherences when describing the excitation state of an atomic system under the influence of anisotropic radiative pumping [e.g., see 14].

Consider a reference system whose Z -axis (the quantization direction of total angular momentum) is chosen along the direction of the applied magnetic field and J -levels whose sublevels are not affected by possible crossings and/or repulsions with the sublevels pertaining to other levels. In this simplest case, the Hanle effect tends to reduce and dephase the quantum coherences with respect to the non-magnetic case, without modifying the population imbalances. For the Hanle effect to operate the magnetic field must be inclined with respect to the symmetry axis of the pumping radiation field. What happens is that as the sublevels are split by the magnetic field, the degeneracy of the J -level under consideration is lifted and the quantum coherences are modified. This gives rise to a characteristic magnetic-field dependence of the linear polarization of the emergent spectral line radiation that provides an attractive diagnostic tool of magnetic fields in astrophysics [e.g., the review by 19].

Typically, in 90° scattering geometry (e.g., when observing off the solar limb) the largest polarization occurs for the unmagnetized case, with the direction of the linear polarization perpendicular to the scattering plane. In the presence of a magnetic field pointing either towards the observer (case **a**) or away from him/her (case **b**) the polarization amplitude is significantly reduced with respect to the unmagnetized case. Moreover, the direction of the linear polarization is rotated with respect to the zero field case. Normally, this rotation is counterclockwise for case (**a**) and clockwise for case (**b**). Therefore, when opposite magnetic polarities coexist within the spatio-temporal resolution element of the observation the direction of the linear polarization is like in the unmagnetized reference case, simply because the rotation effect cancels out. However, the polarization amplitude is indeed reduced with respect to the zero field reference case, which provides an “observable” that can be used to obtain information on hidden, tangled magnetic fields at subresolution scales in the solar atmosphere [see 13, 5].

On the other hand, in forward scattering geometry (e.g., when the line of sight points to solar disk center) we normally have zero polarization in the absence of magnetic fields, while the largest linear polarization (oriented parallel or perpendicular to the direction of the magnetic field) is found for a horizontal field with a strength such that the ensuing Zeeman splitting is sensibly larger than the level’s natural width. In forward scattering geometry the linear polarization is created by the Hanle effect, a physical phenomenon that has been demonstrated to operate on the Sun via spectropolarimetric observations of coronal filaments in the He I 10830 Å multiplet [see 17]. Another very

⁵ If the atom under consideration has non-zero nuclear angular momentum then a rigorous modeling of the spectral line polarization requires taking into account the hyperfine structure, which drastically increases the number of density matrix elements required to specify the excitation state.

interesting example is shown in the right panel of Figure 4.

Approximately, the amplitude of the emergent spectral line polarization is sensitive to magnetic strengths between $0.1 B_H$ and $10 B_H$, where the critical Hanle field intensity (B_H , in gauss) is that for which the Zeeman splitting of the J -level under consideration is equal to its natural width:

$$B_H = 1.137 \times 10^{-7} / (t_{\text{life}} g_J) \quad (2)$$

with t_{life} the lifetime, in seconds, of the J -level under consideration and g_J its Landé factor. If the line's lower level is the ground level or a metastable level, its $t_{\text{life}}(J_l) \approx 1 / (B_{lu} J_0^0) \approx 1 / (\bar{n} A_{ul})$ (with $\bar{n} = c^2 J_0^0 / (2h\nu^3)$ being the solid-angle average of the number of photons per mode at the frequency of the line under consideration and B_{lu} and A_{ul} the Einstein's coefficients). For relatively strong solar spectral lines $t_{\text{life}}(J_l)$ is typically between a factor 10^2 and 10^3 larger than the upper-level lifetime ($t_{\text{life}}(J_u) \approx 1 / A_{ul}$, where A_{ul} is Einstein's coefficient for the spontaneous emission process). For this reason, in solar-like atmospheres *the lower-level Hanle effect* is normally sensitive to magnetic fields in the milligauss range, while *the upper-level Hanle effect* is sensitive to fields in the gauss range.

4. THE NON-LTE PROBLEM OF THE 2ND KIND

The generation and transfer of polarized radiation in a (generally magnetized) astrophysical plasma is a very involved *non-local* and *non-linear* RT problem which requires jointly solving the statistical equilibrium equations for the elements of the atomic density matrix and the Stokes-vector transfer equation for each of the allowed transitions in the chosen multilevel model. Once the selfconsistent values of the elements of the atomic density matrix are known at each point within the medium, it is straightforward to solve the Stokes vector transfer equation in order to obtain the emergent Stokes profiles. At present, there are two computer programs for solving non-LTE problems of the 2nd kind [see 20, 21]. Both codes are based on the formal solvers and the iterative methods proposed by Trujillo Bueno for the numerical solution of non-LTE polarization transfer problems [see 16, 3].

4.1. The Stokes-vector transfer equation

In the polarized case, instead of the standard RT equation for the specific intensity $I(\nu, \vec{\Omega})$ one has to solve, in general, the following *vectorial* transfer equation for the Stokes vector $\mathbf{I}(\nu, \vec{\Omega}) = (I, Q, U, V)^{\dagger}$ ($\dagger$ = transpose):

$$\frac{d}{ds} \mathbf{I} = \boldsymbol{\varepsilon} - \mathbf{K} \mathbf{I}, \quad (3)$$

where s measures the geometrical distance along the ray of direction $\vec{\Omega}$, $\boldsymbol{\varepsilon}$ is the emission vector, and $\mathbf{K}$ the propagation matrix. The elements of the emission vector (that is, ε_I , ε_Q , ε_U , and ε_V) account for the contribution of the *spontaneous emission* process

to the intensity and polarization that is generated at each spatial point by the physical mechanisms under consideration. The propagation matrix $\mathbf{K}$ can be written as

$$\begin{pmatrix} \eta_I & 0 & 0 & 0 \\ 0 & \eta_I & 0 & 0 \\ 0 & 0 & \eta_I & 0 \\ 0 & 0 & 0 & \eta_I \end{pmatrix} + \begin{pmatrix} 0 & \eta_Q & \eta_U & \eta_V \\ \eta_Q & 0 & 0 & 0 \\ \eta_U & 0 & 0 & 0 \\ \eta_V & 0 & 0 & 0 \end{pmatrix} + \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & \rho_V & -\rho_U \\ 0 & -\rho_V & 0 & \rho_Q \\ 0 & \rho_U & -\rho_Q & 0 \end{pmatrix}, \quad (4)$$

which helps to clarify that it has three contributions: absorption (the first matrix, $\mathbf{K}_1$, which is responsible for the attenuation of the radiation beam irrespective of its polarization state), dichroism (the second matrix, $\mathbf{K}_2$, which accounts for a selective absorption of the different polarization states), and dispersion (the third matrix, $\mathbf{K}_3$, which describes the dephasing of the different polarization states as the radiation beam propagates through the medium). Actually, the situation is more complicated (and interesting!) because in general the *propagation* matrix is the difference of two matrices: $\mathbf{K} = \mathbf{K}^A - \mathbf{K}^S$, where $\mathbf{K}^A$ is the above-mentioned contribution resulting from transitions from the lower-level towards the upper-level, while $\mathbf{K}^S$ is the contribution caused by stimulated emission processes. Thus, $\mathbf{K}_1^S$ would be the amplification matrix (responsible for the amplification of the radiation beam irrespective of its polarization state), $\mathbf{K}_2^S$ would be the dichroism matrix (responsible of a selective stimulated emission of different polarization states), and $\mathbf{K}_3^S$ would be the corresponding dispersion matrix. Taking $\mathbf{K}_2^S$ and $\mathbf{K}_3^S$ into account may be of great interest for new discoveries in the field of astronomical masers [e.g., 22].

The general expressions of the components of the emission vector and of the propagation matrix are very involved and will not be written here [see Chapter 7 of 14]. They are given in terms of the ρ_Q^K multipolar components of the atomic density matrix ($K = 0, 1, 2$ and $-K \leq Q \leq K$) corresponding to the upper and lower levels of the line transition under consideration and of line-shape profiles, whose dependence on the magnetic quantum numbers cannot be neglected when the Zeeman splittings are a significant fraction of the spectral line width. Fortunately, such general expressions simplify considerably for several cases of practical interest. For instance, the following are the expressions of the only non-zero emission coefficients for the case of a one-dimensional atmosphere, either unmagnetized, or permeated by a *microturbulent* and *isotropically distributed* magnetic field of strength B , or in the presence of a magnetic field with a fixed orientation but with a strength in the saturation regime of the Hanle effect⁶:

$$\varepsilon_I^{\text{line}} = \varepsilon_0 [\rho_0^0 + w_{J_u J_\ell}^{(2)} \frac{1}{2\sqrt{2}} (3\mu^2 - 1) \rho_0^2], \quad (5)$$

$$\varepsilon_Q^{\text{line}} = \varepsilon_0 w_{J_u J_\ell}^{(2)} \frac{3}{2\sqrt{2}} (1 - \mu^2) \rho_0^2, \quad (6)$$

⁶ In this regime the quantum coherences turn out to vanish in a reference system whose quantization axis is parallel to the magnetic field vector (i.e. the real and imaginary parts of the ρ_1^2 and ρ_2^2 components are zero).

where the ρ_0^K ($K = 0, 2$) values are those of the *upper* level of the line transition under consideration, $\varepsilon_0 = (h\nu/4\pi)A_{ul}\phi_x(2J_u + 1)^{1/2}\mathcal{N}$ (with h , $\mathcal{N}$ and ϕ_x being, respectively, the Planck constant, the particle density and the normalized line profile, with x the frequency distance from the line center in units of the Doppler width), $w_{J_u J_l}^{(2)}$ is the previously mentioned numerical factor that only depends on the quantum numbers of the levels involved in the transition, and where the orientation of the ray is specified by the azimuthal angle χ and by $\mu = \cos\theta$ (with θ the angle between the direction of the radiation beam and the quantization axis, which must be the magnetic field direction itself for the deterministic field case and the normal to the surface of the stellar atmospheric model for the two other cases). Likewise, the only non-zero elements of the propagation matrix are η_I and η_Q which are given by identical expressions (i.e. by $\eta_I = \varepsilon_I$ and $\eta_Q = \varepsilon_Q$), but with $\eta_0 = (h\nu/4\pi)B_{lu}\phi_x(2J_l + 1)^{1/2}\mathcal{N}$ instead of ε_0 , $w_{J_l J_u}^{(2)}$ instead of $w_{J_u J_l}^{(2)}$ and with the ρ_0^K values of the *lower* level of the line transition instead of those of the upper level (for the case in which stimulated emissions are neglected). Note that ε_I and η_I depend on both the level's overall population (ρ_0^0) and the population imbalances (ρ_0^2), while ε_Q and η_Q depend only on the population imbalances (ρ_0^2)⁷.

Under such assumptions a very useful formula can be derived to estimate the emergent fractional linear polarization amplitude at the center of a spectral line:

$$\frac{Q}{I} \approx \frac{\varepsilon_Q/\varepsilon_I - \eta_Q/\eta_I}{1 - (\eta_Q/\eta_I)(\varepsilon_Q/\varepsilon_I)}, \quad (7)$$

where ε_I , ε_Q , η_I and η_Q must be evaluated at height in the model atmosphere where the line-center optical depth is unity along the line of sight. This expression can be simplified taking into account the low polarization level in solar-like atmospheres (i.e., that $\eta_Q/\eta_I \ll 1$ and $\varepsilon_Q/\varepsilon_I \ll 1$). Thus, to first order in $\varepsilon_Q/\varepsilon_I$ and η_Q/η_I , the fractional polarization reduces to $Q/I \approx \varepsilon_Q/\varepsilon_I - \eta_Q/\eta_I$, which leads directly to the approximate Eq. (1). Its first term is due to *selective emission* of polarization components (caused by the population imbalances of the upper level), while its second term is due to “zero-field” dichroism (i.e., it is caused by the *selective absorption* of polarization components produced by the population imbalances of the lower level). Eq. (1) is very useful for understanding that, in general, the second solar spectrum is produced by such two contributions [see 23].

4.2. The rate equations for the elements of the atomic density matrix

We need also to consider the master equation for the atomic density matrix [see 24, 14]. Perhaps, the simplest and most famous example of this approach is that formulated by Einstein, who in 1917 introduced rate equations describing the effect of absorption, stimulated emission, and spontaneous emission processes in a two-level atom. The

⁷ In these expressions, the reference direction for $Q > 0$ is the perpendicular to the plane formed by the propagation direction and the Z-axis.

situation is considerably more complex (and interesting!) in the present polarized case in which we have *atomic and light polarization* instead of simply overall populations of the atomic levels and intensity. In general, we have:

$$\frac{d}{dt}\rho_Q^K(J) = \left[\frac{d}{dt}\rho_Q^K(J)\right]_{\text{MagneticFields}} + \left[\frac{d}{dt}\rho_Q^K(J)\right]_{\text{Radiation}} + \left[\frac{d}{dt}\rho_Q^K(J)\right]_{\text{Collisions}}, \quad (8)$$

where the first two terms on the RHS are the contributions due to a magnetic field (e.g., via the Hanle effect) and to radiative transitions, while the last term is that due to collisions. In order to calculate the ρ_Q^K unknowns at each grid point of the chosen atmospheric model one usually assumes statistical equilibrium (i.e., $d\rho_Q^K(J)/dt = 0$).

The quantum theory of spectral line polarization considered here assumes that the absorption and re-emission processes are statistically independent events. When the only significant quantum coherences are those between the sublevels pertaining to each degenerate level, this complete redistribution theory [see 14] provides a suitable description if the pumping radiation has no spectral structure across a frequency interval larger than both the Larmor frequency (see below) and the natural width of the atomic levels.

Of great interest is the Hanle-effect contribution of Eq. (8), which in the magnetic field reference frame reads [e.g., Eq. 7.11 in 14]

$$\left[\frac{d}{dt}\rho_Q^K(J)\right]_{\text{Hanle}} = -2\pi i \nu_L g_J Q \rho_Q^K(J), \quad (9)$$

where the Larmor frequency $\nu_L = 1.3996 \times 10^6 B$ (with B expressed in gauss) and g_J is the Landé factor of the J -level under consideration. This expression, which is valid for the case of a multilevel atom assuming that quantum coherences can exist *only* between the magnetic sublevels pertaining to each individual J -level, indicates that *in the magnetic field reference system* the population imbalances (i.e. the ρ_Q^K density-matrix elements with $Q = 0$) are insensitive to the intensity of the magnetic field, while the coherences (i.e. the ρ_Q^K elements with $Q \neq 0$) are reduced and dephased as the magnetic field strength increases. In fact, when the Zeeman splitting is much larger than the inverse lifetime of the shortest lived levels (e.g., when $B > B_{\text{sat}}(J_u) \approx 10 B_H(J_u)$) such coherences vanish in the magnetic field reference system.

Certainly isotropic collisions with electrons and ions contribute to the rate of change of the $\rho_Q^K(J)$ elements, but the most relevant effect in solar-like atmospheres comes typically from isotropic *elastic* collisions with neutral hydrogen atoms which induce transitions between the magnetic sublevels pertaining to the J -level under consideration. It can be shown that for isotropic elastic collisions one has [e.g., see Eq. 7.101 in 14]

$$\left[\frac{d}{dt}\rho_Q^K(J)\right]_{\text{ElasticCollisions}} = -D^{(K)}(J) \rho_Q^K(J), \quad (10)$$

where $D^{(K)}(J)$ is the depolarizing rate (in s^{-1}) whose value is proportional to the neutral hydrogen number density. Obviously $D^{(0)}(J) = 0$, and the effect on the $\rho_Q^K(J)$ elements with $K > 0$ will be significant when $\delta^{(K)}(J) = D^{(K)}(J) t_{\text{life}}(J) \approx 1$, where $t_{\text{life}}(J)$ is that defined after Eq. (2).

Finally, the contribution caused by radiative transitions includes the *transfer* rates due to absorption (T_A), spontaneous emission (T_E) and stimulated emission (T_S) from other levels, and the *relaxation* rates due to absorption (R_A), spontaneous emission (R_E) and stimulated emission (R_S) towards other levels. The general expressions are rather complicated [see, e.g., §7.2.a of 14], but the following ones are of great practical interest even though they neglect the stimulated emission rates and correspond to the particular case of a one-dimensional atmosphere, either unmagnetized or in the presence of a deterministic magnetic field with a fixed orientation but with a strength in the saturation regime of the Hanle effect⁸:

$$\begin{aligned} \left[\frac{d}{dt} \rho_0^K(J) \right]_{\text{Radiation}} = & \sum_{J_l} \sum_{K_l} \rho_0^{K_l}(J_l) T_A(J_l; K_l \rightarrow J; K) \\ & + \sum_{J_u} \sum_{K_u} \rho_0^{K_u}(J_u) T_E(J_u; K_u \rightarrow J; K) \\ & - \sum_{K'} \rho_0^{K'}(J) [R_A(J; K, K' \rightarrow J_u) + R_E(J; K, K' \rightarrow J_l)], \quad (11) \end{aligned}$$

where $K_l = 0, 2, 4, \dots, 2J_l$; $K_u = 0, 2, 4, \dots, 2J_u$ and $K' = 0, 2, 4, \dots, 2J$.

Of particular interest are the transfer rate T_A due to *absorption* from lower levels and the relaxation rate R_A due to absorptions toward upper levels. Their expressions are given by linear combinations of the $\bar{J}_0^0$ and $\bar{J}_0^2$ radiation field tensors [see Eqs. 7.14a and 7.14d in 14]. Note that $\bar{J}_0^0$ is the familiar $\bar{J}$ -quantity of the standard non-LTE problem of the 1st kind (which is an average over frequencies and directions of the Stokes I parameter weighted by the absorption profile), while⁹

$$\bar{J}_0^2 = \int dx \oint \phi_x \frac{d\vec{\Omega}}{4\pi} \frac{1}{2\sqrt{2}} [(3\mu^2 - 1)I_{x\vec{\Omega}} + 3(\mu^2 - 1)Q_{x\vec{\Omega}}]. \quad (12)$$

5. AN INTERESTING EFFECT: MAGNETIC MODULATION OF THE POPULATION RATIO

Equations (11) imply that even the ratio $\mathcal{N}_u/\mathcal{N}_l$ of the populations of the upper and lower levels of a spectral line may depend on the $\bar{J}_0^2$ tensor component (which quantifies the “anisotropy” of the radiation field), and not only on $\bar{J}_0^0$. Even more interesting is the fact that the $\mathcal{N}_u/\mathcal{N}_l$ value is modulated by the inclination of the magnetic field with respect to the symmetry axis of the incident radiation field (hereafter, the vertical axis). In order to illustrate this remarkable phenomenon let us consider the case of anisotropic radiation pumping in a gas composed by two-level atoms with $J_l = 1$ and $J_u = 0$ in

⁸ It is important to note that in this last case the multipolar components, $\rho_Q^K(J)$, and the radiation field tensors, $\bar{J}_Q^K$, have to be defined in the magnetic field reference frame.

⁹ In the most general case the number of $\bar{J}_Q^K$ tensors necessary to quantify the symmetry properties of the radiation field is 9 [see §5.11 in 14] [see also Fig. 3 in 25].

the presence of a deterministic magnetic field inclined by an angle θ_B with respect to the vertical axis and with a strength $B > B_{\text{sat}}(J_l) \approx 10 B_H(J_l)$, so that all the quantum coherences between the magnetic sublevels of the lower level are zero in the magnetic field reference frame. In this Hanle effect saturation regime the statistical equilibrium equations in the magnetic field reference frame are identical to those corresponding to the unmagnetized case [see Eqs. 3–5 in 15], with the only difference that J_0^2 has to be substituted by:

$$[\bar{J}_0^2]_B = \frac{1}{2}(3\cos^2\theta_B - 1)[\bar{J}_0^2]_V, \quad (13)$$

where $[\bar{J}_0^2]_B$ and $[\bar{J}_0^2]_V$ are the $\bar{J}_0^2$ radiation field tensor in the magnetic field and in the “vertical” reference frames, respectively. Neglecting the contribution of inelastic collisions in Eq. (3) of [15] one obtains

$$\frac{\mathcal{N}_u}{\mathcal{N}_l} = \frac{\bar{n}}{3} \left(1 - \frac{1}{\sqrt{2}} [w]_B [\sigma_0^2(J_l)]_B \right), \quad (14)$$

where $\bar{n} = \bar{J}_0^0(2J_l + 1)B_{lu}/(2J_u + 1)A_{ul}$ is the average of the number of photons per mode of the incident radiation at the line frequency and $[w]_B = \sqrt{2}[\bar{J}_0^2]_B/\bar{J}_0^0$ is the anisotropy factor in the magnetic field reference frame. In Eq. (14) $[\sigma_0^2(J_l)]_B = [\rho_0^2(l)]_B/\rho_0^0(l)$ is the fractional atomic alignment of the lower-level in the magnetic field reference frame, which can be easily calculated by neglecting inelastic collisions in Eq. (4) of [15]. Disregarding also for simplicity elastic collisions and using the ensuing expression in Eq. (14) it is easy to find that for a two-level atom with $J_l = 1$ and $J_u = 0$

$$\frac{\mathcal{N}_u}{\mathcal{N}_l} = \frac{\bar{n}}{3} \left[1 - \frac{(3\cos^2\theta_B - 1)^2 w^2 / 2}{4 - (3\cos^2\theta_B - 1)w} \right]. \quad (15)$$

The lower curve in Fig. 6 shows the variation with θ_B of $\mathcal{N}_u/\mathcal{N}_l$ for this case of a resonance line transition with $J_l = 1$ and $J_u = 0$, assuming $\bar{n} = 10^{-4}$ (which implies that the rates of stimulated emission can indeed be neglected) and $w = 0.99$ (i.e., that the atomic system is irradiated by an almost collimated radiation beam)¹⁰. Note that when $w = 1$ the upper level is fully depopulated if the magnetic field is parallel to the incident beam of unpolarized radiation (i.e., if $\theta_B = 0^\circ$ or $\theta_B = 180^\circ$). This occurs because, under such anisotropic pumping conditions, all atoms end up in the $M_l = 0$ sublevel of the lower level and the medium becomes transparent. The same happens in the absence of magnetic fields, a well-known effect in the quantum optics literature [e.g., 26].

A similar but more involved analytical expression for $\mathcal{N}_u/\mathcal{N}_l$ can also be derived for the case of a resonance line transition with $J_l = J_u = 1$, but assuming now that $B > B_{\text{sat}}(J_u) \approx 10 B_H(J_u)$. To this end it suffices with using the statistical equilibrium equations for the case of a two-level atom with $J_l = J_u = 1$ [see 16, 3]. The upper curve in Fig. 6 shows the ensuing results. Note that for this case $\mathcal{N}_u/\mathcal{N}_l = \bar{n} = 10^{-4}$ when

¹⁰ It is of interest to point out that such values for $\bar{n}$ and w are very similar to those corresponding to the 10830 Å solar continuum radiation at a distance of 10 solar radii above the visible stellar surface.

FIGURE 6. Variation of the indicated population ratio with the inclination of the magnetic field vector with respect to the symmetry axis of the incident radiation. This radiation has $\bar{n} = 10^{-4}$ and $w = [w]_V = 0.99$. The strength of the magnetic field is assumed to be sufficiently high so as to produce saturation of the Hanle effect for the spectral line under consideration (e.g., only 0.1 G for the line with $J_u = 0$ and 100 G for the line with $J_l = J_u = 1$). The dashed line indicates the $\bar{n}/3$ value.

$[w]_B = 0$ (which is always the case at $\theta_B = 54.74^\circ$ and $\theta_B = 125.26^\circ$, the so-called Van-Vleck angles).

As seen in Fig. 6, for both line transitions the population ratio $\mathcal{N}_u/\mathcal{N}_l$ depends on the inclination of the magnetic field with respect to the symmetry axis of the pumping radiation field. Note that for the operation of this interesting effect in astrophysical environments where the stimulated emission terms are negligible (i.e., because $\bar{n} \ll 1$) the lower level of the line transition under consideration must be polarized. However, if stimulated emission radiation is significant (i.e., because $\bar{n} \sim 1$) then such a modulation takes place even in line transitions whose lower-level is unpolarized, such as in a spectral line with $J_l = 0$ and $J_u = 1$.

6. CONCLUDING COMMENTS

As mentioned in §1, we may define *the Sun's hidden magnetism* as all the magnetic fields of the extended solar atmosphere that are impossible to diagnose via the consideration of the Zeeman effect alone. Contrary to what one might think, there are many examples that belong to this category:

- The greater part of the magnetism of the quiet solar photosphere.
- The magnetic fields of the solar chromosphere outside sunspots.
- The magnetic fields that confine the plasma of solar prominences and filaments.
- The magnetism of the solar transition region and corona.

Fortunately, the Hanle and Zeeman effects can be suitably complemented for exploring magnetic fields in solar and stellar physics. To this end, it is necessary to interpret

high-sensitivity spectropolarimetric observations through the numerical solution of non-LTE problems of the 2nd kind. The interested reader will find abundant information on a variety of interesting applications in solar physics in the following review papers: [27, 28, 23, 29].

Finally, it is important to emphasize that one of the greatest challenges in astrophysics is the empirical investigation of the magnetic field vector in a variety of astrophysical systems, such as the solar corona, circumstellar envelopes, accreting systems, etc. The physical mechanisms I have considered here (anisotropic radiative pumping, atomic level polarization and the Hanle and Zeeman effects) occur in many astrophysical environments, not only in the solar atmosphere. In particular, the linear polarization signals produced by the presence of atomic level polarization are sensitive to magnetic fields in a parameter domain that ranges from very weak fields (e.g., 1 mG) to a few hundred gauss. The observation and physical interpretation of these polarization effects via the solution of the non-LTE problem of the 2nd kind provides key information, impossible to obtain via spectroscopy or conventional spectropolarimetry.

ACKNOWLEDGMENTS

Financial support by the Spanish Ministry of Science and Innovation through project AYA2007-63881 and by the European Commission via the SOLAIRE network (MTRN-CT-2006-035484) are gratefully acknowledged. The author is also grateful to the members of the SOC for their invitation to participate in a very good conference.
